

Standard Test Method for Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites¹

This standard is issued under the fixed designation C 1341; the number immediately following the designation indicates the year of original adoption or, in the case of revision, the year of last revision. A number in parentheses indicates the year of last reapproval. A superscript epsilon (ε) indicates an editorial change since the last revision or reapproval.

1. Scope

1.1 This test method covers the determination of flexural properties of continuous fiber-reinforced ceramic composites in the form of rectangular bars formed directly or cut from sheets, plates, or molded shapes. Three test geometries are described as follows:

1.1.1 *Test Geometry I*—A three-point loading system utilizing center point force application on a simply supported beam.

1.1.2 *Test Geometry IIA*—A four-point loading system utilizing two force application points equally spaced from their adjacent support points with a distance between force application points of one half of the support span.

1.1.3 *Test Geometry IIB*—A four-point loading system utilizing two force application points equally spaced from their adjacent support points with a distance between force application points of one third of the support span.

1.2 This test method applies primarily to all advanced ceramic matrix composites with continuous fiber reinforcement: uni-directional (1-D), bi-directional (2-D), tri-directional (3-D), and other continuous fiber architectures. In addition, this test method may also be used with glass (amorphous) matrix composites with continuous fiber reinforcement. However, flexural strength cannot be determined for those materials that do not break or fail by tension or compression in the outer fibers. This test method does not directly address discontinuous fiber-reinforced, whisker-reinforced, or particulate-reinforced ceramics. Those types of ceramic matrix composites are better tested in flexure using Test Methods C 1161 and C 1211.

1.3 Tests can be performed at ambient temperatures or at elevated temperatures. At elevated temperatures, a suitable furnace is necessary for heating and holding the test specimens at the desired testing temperatures.

1.4 This test method includes the following:

3. Terminology

3.1 Definitions—The definitions of terms relating to flexure testing appearing in Terminology **E 6** apply to the terms used in this test method. The definitions of terms relating to advanced ceramics appearing in Terminology **C 1145** apply to the terms used in this test method. The definitions of terms relating to fiber-reinforced composites appearing in Terminology **D 3878** apply to the terms used in this test method. Pertinent definitions as listed in Test Method **C 1161**, Test Methods **D 790**, Terminology **C 1145**, Terminology **D 3878**, and Terminology **E 6** are shown in the following with the appropriate source given in brackets. Additional terms used in conjunction with this test method are also defined in the following.

3.1.1 *advanced ceramic, n*—highly engineered, high-performance, predominately nonmetallic, inorganic, ceramic material having specific functional attributes. **C 1145**

3.1.2 *breaking force, n [F]*—The force at which fracture occurs. (In this test method, fracture consists of breakage of the test bar into two or more pieces or a loss of at least 20 % of the maximum force carrying capacity.) **E 6**

3.1.3 *ceramic matrix composite, n*—material consisting of two or more materials (insoluble in one another) in which the major, continuous component (matrix component) is a ceramic, while the secondary component(s) (reinforcing component) may be ceramic, glass-ceramic, glass, metal, or organic in nature. These components are combined on a macroscale to form a useful engineering material possessing certain properties or behavior not possessed by the individual constituents.

3.1.4 *continuous fiber-reinforced ceramic composite (CFCC), n*—ceramic matrix composite in which the reinforcing phase consists of a continuous fiber, continuous yarn, or a woven fabric.

3.1.5 *flexural strength, n [FL⁻²]*—measure of the ultimate strength of a specified beam in bending. **C 1161**

3.1.6 *four-point-1/3 point flexure, n*—a configuration of flexural strength testing where a test specimen is symmetrically loaded at two locations that are situated one third of the overall span away from the outer two support bearings.

3.1.7 *four-point-1/4 point flexure, n*—a configuration of flexural strength testing where a test specimen is symmetrically loaded at two locations that are situated one quarter of the overall span away from the outer two support bearings.

C 1161

3.1.8 *fracture strength, n [FL⁻²]*—the calculated flexural stress at the breaking force.

3.1.9 *modulus of elasticity, n [FL⁻²]*—the ratio of stress to corresponding strain below the proportional limit. **E 6**

3.1.10 *proportional limit stress, n [FL⁻²]*—greatest stress that a material is capable of sustaining without any deviation from proportionality of stress to strain (Hooke’s law).

3.1.10.1 *Discussion*—Many experiments have shown that values observed for the proportional limit vary greatly with the sensitivity and accuracy of the testing equipment, eccentricity of force application, the scale to which the stress-strain diagram is plotted, and other factors. When determination of proportional limit is required, the procedure and sensitivity of the test equipment shall be specified. **E 6**

3.1.11 *slow crack growth, n*—subcritical crack growth (extension) that may result from, but is not restricted to, such mechanisms as environmentally assisted stress corrosion or diffusive crack growth.

3.1.12 *span-to-depth ratio, n [nd]*—for a particular test specimen geometry and flexure test configuration, the ratio (L/d) of the outer support span length (L) of the flexure test specimen to the thickness/depth (d) of test specimen (as used and described in Test Method **D 790**).

3.1.13 *three-point flexure, n*—a configuration of flexural strength testing where a test specimen is loaded at a location midway between two support bearings. **C 1161**

4. Summary of Test Method

4.1 A bar of rectangular cross section is tested in flexure as a beam as in one of the following three geometries:

4.1.1 *Test Geometry I*—The bar rests on two supports and force is applied by means of a loading roller midway between the supports (see Fig. 1.)

4.1.2 *Test Geometry IIA*—The bar rests on two supports and force is applied at two points (by means of two inner rollers), each an equal distance from the adjacent outer support point.

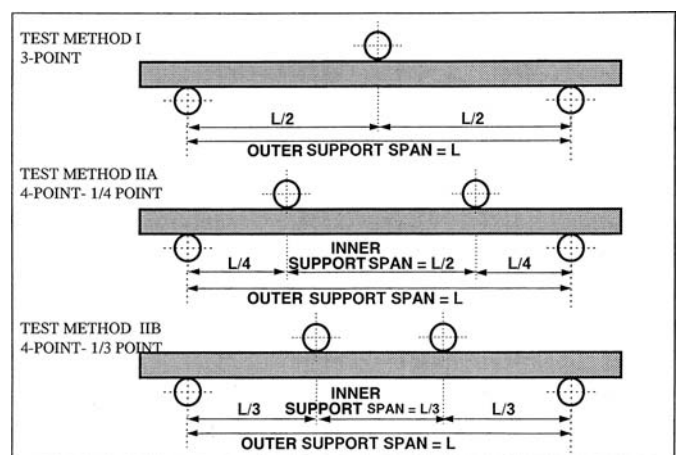

FIG. 1 Flexural Test Geometries

The inner support points are situated one quarter of the overall span away from the outer two support bearings. The distance between the inner rollers (that is, the load span) is one half of the support span (see Fig. 1).

4.1.3 *Test Geometry IIB*—The bar rests on two supports and force is applied at two points (by means of two loading rollers), situated one third of the overall span away from the outer two support bearings. The distance between the inner rollers (that is, the inner support span) is one third of the outer support span (see Fig. 1).

4.2 The test specimen is deflected until rupture occurs in the outer fibers or until there is a 20 % decrease from the peak force.

4.3 The flexural properties of the test specimen (flexural strength and strain, fracture strength and strain, modulus of elasticity, and stress-strain curves) are calculated from the force and deflection using elastic beam equations.

5. Significance and Use

5.1 This test method is used for material development, quality control, and material flexural specifications. Although flexural test methods are commonly used to determine design strengths of monolithic advanced ceramics, the use of flexure test data for determining tensile or compressive properties of CFCC materials is strongly discouraged. The nonuniform stress distributions in the flexure test specimen, the dissimilar mechanical behavior in tension and compression for CFCCs, low shear strengths of CFCCs, and anisotropy in fiber architecture all lead to ambiguity in using flexure results for CFCC material design data (1-4). Rather, uniaxial-forced tensile and compressive tests are recommended for developing CFCC material design data based on a uniformly stressed test condition.

5.2 In this test method, the flexure stress is computed from elastic beam theory with the simplifying assumptions that the material is homogeneous and linearly elastic. This is valid for composites where the principal fiber direction is coincident/transverse with the axis of the beam. These assumptions are necessary to calculate a flexural strength value, but limit the application to comparative type testing such as used for material development, quality control, and flexure specifications. Such comparative testing requires consistent and standardized test conditions, that is, test specimen geometry/thickness, strain rates, and atmospheric/test conditions.

5.3 Unlike monolithic advanced ceramics which fracture catastrophically from a single dominant flaw, CFCCs generally experience “graceful” fracture from a cumulative damage process. Therefore, the volume of material subjected to a uniform flexural stress may not be as significant a factor in determining the flexural strength of CFCCs. However, the need to test a statistically significant number of flexure test specimens is not eliminated. Because of the probabilistic nature of the strength of the brittle matrices and of the ceramic fiber in CFCCs, a sufficient number of test specimens at each testing condition is required for statistical analysis, with guidelines for sufficient numbers provided in 9.7. Studies to determine the exact influence of test specimen volume on strength distributions for CFCCs are not currently available.

5.4 The four-point loading geometries (Geometries IIA and IIB) are preferred over the three-point loading geometry (Geometry I). In the four-point loading geometry, a larger portion of the test specimen is subjected to the maximum tensile and compressive stresses, as compared to the three-point loading geometry. If there is a statistical/Weibull character failure in the particular composite system being tested, the size of the maximum stress region will play a role in determining the mechanical properties. The four-point geometry may then produce more reliable statistical data.

5.5 Flexure tests provide information on the strength and deformation of materials under complex flexural stress conditions. In CFCCs nonlinear stress-strain behavior may develop as the result of cumulative damage processes (for example, matrix cracking, matrix/fiber debonding, fiber fracture, delamination, etc.) which may be influenced by testing mode, testing rate, processing effects, or environmental influences. Some of these effects may be consequences of stress corrosion or subcritical (slow) crack growth which can be minimized by testing at sufficiently rapid rates as outlined in 10.3 of this test method.

5.6 Because of geometry effects, the results of flexure tests of test specimens fabricated to standardized test dimensions from a particular material or selected portions of a component, or both, cannot be categorically used to define the strength and deformation properties of the entire, full-size end product or its in-service behavior in different environments. The effects of size and geometry shall be carefully considered in extrapolating the test results to other configurations and performance conditions.

5.7 For quality control purposes, results from standardized flexure test specimens may be considered indicative of the response of the material lot from which they were taken with the given primary processing conditions and post-processing heat treatments.

5.8 The flexure behavior and strength of a CFCC are dependent on its inherent resistance to fracture, the presence of fracture sources, or damage accumulation processes or combination thereof. Analysis of fracture surfaces and fractography, though beyond the scope of this test method, is highly recommended.

6. Interferences

6.1 A CFCC material tested in flexure may fail in a variety of distinct fracture modes, depending on the interaction of the nonuniform stress fields in the flexure test specimen and the local mechanical properties. The test specimen may fail in tension, compression, shear, or in a mix of different modes, depending on which mode reaches the critical stress level for failure to initiate. To obtain a valid flexural strength by this test method, the material must fail in the outer fiber surface in tension or compression, rather than by shear failure. The geometry of the test specimen must be chosen so that shear stresses are kept low relative to the tension and compression stresses. This is done by maintaining a high ratio between the support span (L) and the thickness/depth (d) of the test specimen. This L/d ratio is generally kept at values of ≥ 16 for 3-point testing and ≥ 30 for 4-point testing. If the span-to-depth ratio is too low, the test specimen may fail in shear, invalidating

the test. If the desired mode of failure is shear, then an appropriate shear test method should be used, such as Test Method [C 1292](#) or [D 2344/D 2344M](#).

6.2 Time-dependent phenomena, such as stress corrosion and slow crack growth, can interfere with the determination of the flexural strength at room and elevated temperatures. Creep phenomena also become significant at elevated temperatures. Both mechanisms can cause stress relaxation in flexure test specimens during a strength test, thereby causing the elastic formula calculations to be in error. Test environment (vacuum, inert gas, ambient air, etc.) including moisture content (for example, relative humidity) may have an accelerating effect on stress corrosion and slow crack growth. Testing to evaluate the maximum strength potential of a material should be conducted in inert environments or at sufficiently rapid testing rates, or both, so as to minimize slow crack growth effects. Conversely, testing can be conducted in environments and testing modes and rates representative of service conditions to evaluate material performance under use conditions. When testing is conducted in uncontrolled ambient air with the intent of evaluating maximum strength potential, monitor and report the relative humidity and temperature.

6.3 Surface preparation of test specimens, although normally not considered a major concern in CFCCs, can introduce fracture sources on the surface which may have pronounced effects on flexural mechanical properties and behavior (for example, elastic and nonelastic regions of the stress-strain curve, flexural strength and strain, proportional limit stress and strain, etc.). Machining damage introduced during test specimen preparation can be either a random interfering factor in the determination of flexure strength of test specimen or an inherent part of the strength characteristics being measured. Surface preparation can also lead to the introduction of residual stresses. Universal or standardized test methods of surface preparation for CFCCs do not exist. It should be understood that final machining steps may or may not negate machining damage introduced during the initial machining. Thus, test specimen fabrication history may play an important role in the measured strength distributions and should be reported. In addition, the nature of fabrication used for certain composites (for example, chemical vapor infiltration, hot pressing, and preceramic polymer lamination) may require the testing of specimens in the as-processed condition (that is, it may not be possible or appropriate to machine the test specimen faces).

6.4 Fractures that initiate outside the uniformly stressed region of a flexure test specimen (between the inner support points in four-point and under the center point in three-point) may be due to factors such as stress concentrations or strength limiting features in the microstructure of the test specimen. Fractures which do occur outside the uniformly stressed sections will normally constitute invalid tests. If the flexure data is used in the context of estimating Weibull parameters then appropriate computational methods shall be used for such censored data. These methods are outlined in Practice [C 1239](#).

6.5 Flexural strength at elevated temperature may be strongly dependent on force application rate as consequence of creep, stress corrosion, or slow crack growth effects. This test

method measures the flexural strength at high force application rates in order to minimize these effects.

7. Apparatus

7.1 *Testing Machine*—Test the flexure test specimens in a properly calibrated testing machine that can be operated at constant rates of cross-head motion over the range required. The error in the force measuring system shall not exceed $\pm 1\%$ of the maximum force being measured. The force-indicating mechanism shall be essentially free from inertial lag at the cross-head rate used. Although not recommended, if the cross-head displacement is used to determine the test specimen deflection for the three-point loading geometry, determine the compliance of the load train (see [Appendix X1](#)), so that appropriate corrections can be made to the deflection measurement. Equip the system with a means for retaining the readout of the maximum force as well as a record of force versus time. Verify the accuracy of the testing machine in accordance with Practices [E 4](#).

7.2 *Loading Fixtures*—The outer support span and the desired test geometry determine the dimensions and geometry of the loading fixture. Select the fixture geometry from one of three configurations: 3-point, 4-point- $\frac{1}{4}$ point, and 4-point- $\frac{1}{3}$ point. The thickness of test specimen to be tested determines the critical outer span dimension (L) of the loading fixture. The overall dimensions of the test specimen and the required inner and outer support spans are selected based on the specimen thickness, the desired test geometry, and the required span-to-depth ratio. [Table 1](#), [Table 2](#), and [Table 3](#) give the recommended support spans for different span/depth ratios, test specimen thicknesses, and the three test geometries. Loading fixtures shall be wide enough to support the entire width of the selected test specimen geometry.

7.2.1 Ensure that the design and construction of the fixtures produces even and uniform forces along the bearing-to-specimen surfaces. A rigid loading fixture is permitted, if it is designed and aligned so that forces are evenly applied to the test specimen, particularly for four-point loading geometries. It is preferred, however, that load fixtures with an articulating geometry be used. An articulated loading fixture reduces or eliminates uneven force application caused by geometry variations of the test specimen or misalignment of the test fixtures.

7.2.2 *Semi-Articulating Fixtures*—Test specimens prepared in accordance with and meeting the parallelism requirement of [9.4](#) may be tested in a semi-articulating fixture. The bearing cylinders shall be parallel to each other within 0.1 mm over their length. (A representative design for a four-point fixture is illustrated in [Fig. 2](#).)

7.2.3 *Fully Articulating Fixture*—Test specimens with slight warp, twist, or bowing may not meet the parallelism requirements of [9.4](#). It is recommended that such test specimens be tested in a fully articulating fixture. (A representative design for a four-point fixture is illustrated in [Fig. 3](#).)

7.2.4 The test fixture shall be made of a material that is suitably rigid and resistant to permanent deformation at the forces and temperatures of testing. The test fixture material shall be essentially inert at the desired test temperatures.

7.3 *Inner/Outer/Center Support Bearings*—In both the three-point and four-point flexure test fixtures, use cylindrical

bearings for support of the test specimen and for force application. The cylinders shall be made of a tool steel or a ceramic with an elastic modulus between 200 and 400 GPa and a flexural strength no less than 275 MPa. The inner/outer/center support bearing cylinders shall remain elastic over the force and temperature ranges used.

7.3.1 Ensure that the inner/outer/center support bearings have cylindrical surfaces that are smooth and parallel along their length to an accuracy of ± 0.05 mm. In order to avoid excessive indentation or crushing failure directly under the bearing contact surface, the bearing-surface diameter shall be at least 3.0 mm. The bearing-surface diameter shall be approximately 1.5 times the beam depth of the test specimen size used. If the test specimen has low through-thickness compressive strength, the cylinder diameter shall be four times the beam thickness to prevent crushing at the force application points.

NOTE 1—In such circumstances, however, there is a possible error due

^A Rates indicated are for a strain rate of 0.001 mm/mm-s.

which need not rotate). This can be accomplished as shown in Fig. 2 and Fig. 3. Note that the outer support bearings roll outward, and the inner support bearings roll inward.

NOTE 2—In general, fixed-pin fixtures have frictional constraints that have been shown to cause a systematic error on the order of 5 to 15 % in flexural strength for monolithic ceramics. Since this error is systematic, it will lead to a bias in estimates of mean strength. Rolling-pin fixtures are required for articulating fixtures by this test method. It is recognized that they may not be feasible for rigid fixtures, in which case fixed-pin fixtures may be used. But this shall be stated explicitly in the report.

7.4 *Deflection Measurement*—The test system shall have a means of measuring test specimen deflection, appropriate for the geometry and the test temperature. The preferred device measures actual deflection at the centerline of the test specimen

support span, using direct contact or optical function. The calibrated range of the deflectometer shall be such that the linear strain region of the material tested will represent a minimum of 20 % of the calibrated range. The deflectometer shall have an accuracy of 1 % of the maximum deflection measured.

7.5 *Strain Measurement*—The use of strain gages for ambient testing is acceptable provided that the test material surface is smooth with little open porosity and that the applied strain gage is large enough to cover a representative area of the composite test specimen. Follow the manufacturer's recommendations regarding application and performance. Strain gages shall not interfere with the deflection measuring device.

7.6 *Heating Apparatus*—For elevated-temperature testing, any furnace that meets the temperature uniformity and control requirements described below shall be acceptable. A furnace whose heated cavity is large enough to accept the entire test fixture is preferred.

7.6.1 The furnace shall be capable of establishing and maintaining a constant temperature (within $\pm 5^\circ\text{C}$) during each test period. Measure the temperature uniformity of the test specimen across the inner support span section extending from the center to 5 mm inside the outer support points. The temperature uniformity along the inner support span shall be within $\pm 5^\circ\text{C}$ test temperatures up to and including 500°C and $\pm 1\%$ for test temperatures above 500°C .

7.6.1.1 In order to determine conformance to the temperature control and uniformity requirements, determine a temperature profile using thermocouples to measure the test specimen temperature at three locations—the test specimen center point and two points 5 mm inside the outer support points.

7.6.1.2 Determine temperature uniformity for all elevated-temperature testing and recheck the uniformity if any of the following parameters are changed: heating method, test specimen material, sample geometry, or test temperature, or combination thereof.

7.6.2 *Temperature Measurement*—The use of thermocouples (TC) is recommended and preferred; however, the use of optical pyrometry is acceptable. For TC measurement, elevated-temperature tests require the placement of one TC at the test specimen center. The sheathed TC should be within 1 mm of the test specimen. The use of two additional thermocouples at locations 5 mm inside the outer support points is recommended to check for temperature uniformity. Thermocouples shall be calibrated in accordance with Test Method E 220 with a verified accuracy of $\pm 5^\circ\text{C}$.

7.6.3 *Atmosphere Control*—The furnace may have an air, inert, or vacuum environment, as required. If an inert or vacuum environment is used, and it is necessary to apply force through a bellows, fitting, or seal, verify that force losses or errors do not exceed 1 % of the expected failure forces.

7.7 *Data Acquisition*—At the minimum, obtain an autographic record of the applied force and center-point deflection or sample strain versus time for the specified cross-head rate. Either analog chart recorders or digital data acquisition systems may be used for this purpose, although a digital record is recommended for ease of subsequent data analysis. Ideally, an analog chart recorder or plotter should be used in conjunction

FIG. 2 Semi-Articulating Flexure Fixtures

with the digital data acquisition system to provide an immediate record of the test as a supplement to the digital record. Ensure that the recording devices have an accuracy of 0.1 % of full scale and have a minimum data acquisition rate of 10 Hz with a response of 50 Hz deemed more than sufficient.

7.8 *Dimension-Measuring Devices*—Micrometers and other devices used for measuring linear dimensions shall be accurate and precise to at least one half the smallest unit to which the individual dimension is required to be measured. For the purposes of this test method, measure the cross-sectional dimensions to within 0.02 mm with a measuring device with an accuracy of 0.01 mm.

7.9 *Calibration*—Calibration of equipment shall be provided by the supplier with traceability maintained to the National Institute of Standards and Technology (NIST). Recalibration shall be performed with a NIST-traceable standard on all equipment on a six-month interval or whenever accuracy is in doubt.

8. Hazards

8.1 During the conduct of this test method, the possibility of flying fragments of broken test specimens may be high. The brittle nature of advanced ceramics and the release of strain energy contribute to the potential release of uncontrolled

fragments upon fracture. The containment/retention of these fragments for later fractographic reconstruction and analysis is highly recommended.

8.2 Exposed fibers at the edges and faces of CFCC test specimens may present a hazard due to the sharpness and brittleness of the ceramic fibers. Inform all individuals who handle these materials of potential hazards and the proper handling techniques.

9. Test Specimens

9.1 Selection of a specific test specimen geometry depends on many factors—the geometry of available material, the expected mechanical properties, the geometry of the final component, geometry limitations in the test equipment, and cost factors.

9.1.1 Test specimens must have a span-to-depth ratio (L/d) that produces tensile or compressive failure in the outer fiber surfaces of the sample under the bending moment. If the L/d ratio is too low, the sample may fail due to shear stress, producing an invalid test. Three recommended L/d ratios are 16:1, 32:1, and 40:1. Materials with lower shear strength require higher L/d ratios. A 16:1 ratio is a recommended starting point for three-point testing (3). A 32:1 ratio is a recommended starting point for four-point testing (3). For CFCCs with very low interlaminar shear strengths (<3.5 MPa)

NOTE 1—One of the four inner/outer/center support bearings (for example, Roller No. 1) shall not articulate about the x -axis. The other three will provide the necessary degrees of freedom. The radius R in the bottom fixture shall be sufficiently large such that contact stresses on the roller are minimized.

FIG. 3 Fully Articulating Flexure Fixture

based on low matrix density or shear failure at interfaces, L/d ratios of 60 may be necessary to prevent shear failures. If shear failures are observed during initial testing, a modified test geometry with a higher L/d ratio (for example, 40:1 or 60:1) shall be used for subsequent tests.

9.1.2 Prepare the test specimens with dimensions determined from the appropriate tables (Table 1 for three-point bending, Table 2 for four-point- $1/4$ point bending, and Table 3 for four-point- $1/3$ point bending). Determine the minimum dimensions for specimen width and length and the support span based on the test specimen thickness and the desired L/d ratio.

9.1.3 Test specimen width shall not exceed one fourth of the support span for specimens greater than 3 mm in depth. The test specimen shall be long enough to allow for overhang past the outer supports of at least 5 % of the support span, but in no case less than 5 mm on each end. Overhang shall be sufficient to minimize shear failures in the test specimen ends and to prevent the test specimen from slipping through the supports at large center-point deflections.

9.1.4 Ensure that composites with woven fiber architecture have a test specimen width that is equal to or greater than twice the width of the repeating unit of the weave in the width dimension.

9.1.5 Anisotropy in mechanical properties of composites is strongly affected by fiber architecture. Alignment of the long axis of the flexure test specimen with a principal weave direction must be controlled and monitored. Measure the alignment to an angular precision of ± 5 degrees.

9.2 *Fabrication Method*—The test specimens may be cut from sheets, plates, or molded shapes, or may be formed directly to the required finished dimensions.

9.3 *Finishing Method*—Depending upon the application of the strength data, use one of the following test specimen finishing procedures: as-fabricated, application matched, customary, and standard. These finishing details are described in Annex A2. Regardless of the preparation procedure used, sufficient details regarding the procedure shall be reported to allow replication.

9.3.1 For a given set of test specimens cut from a sample panel, prepare and record a cutting diagram showing the location and orientation of individual test specimens with respect to the starting panel geometry and the fiber/fabric orientation.

9.4 *Dimensional Tolerances*—The cross-sectional tolerance for cut/machined dimensions shall be ± 0.1 mm or 0.5 % of the dimension, whichever is greater. Parallelism tolerances on cut/machined faces are 0.02 mm or 0.5 %, whichever is greater.

9.5 *General Examination*—The mechanical responses of CFCCs are strongly affected by geometry, porosity, and discontinuities. Inspect and characterize each test specimen carefully for nonuniformity in major dimensions, warp, twist, and bowing, porosity (volume % and size distribution), discontinuities such as delaminations, cracks, etc., and surface roughness on as-prepared and finished surfaces. Record these observations/measurements and include them in the final report as well as any results of nondestructive evaluation.

9.6 *Handling Precaution*—Exercise care in the storage and handling of finished test specimens to avoid the introduction of random and severe fracture sources. In addition, consider pre-test storage of test specimens in controlled environments or desiccators to avoid unquantifiable environmental degradation of test specimens prior to testing.

9.7 *Number of Test Specimens*—A minimum of ten test specimens is required for the purposes estimating a mean. A greater number of test specimens may be necessary if the estimates regarding the form of the strength distribution are required. If material cost or test specimen availability limits the number of tests to be conducted, fewer tests can be conducted to develop an indication of material properties.

10. Procedure

10.1 *Test Specimen Dimensions*—Determine the thickness and width of each test specimen to within 0.02 mm. Measure the test specimen at least three different cross-sectional planes in the stressed section (between the outer force application points). It is recommended that machined surfaces be measured either optically (for example, by an optical comparator) or mechanically, using a flat, anvil-type micrometer. Measure rough or as-processed surfaces with a double-ball interface micrometer with a ball radius of 4 mm. In all cases the resolution of the instrument shall meet the requirements specified in 7.8. Measure the test specimens with care to prevent surface damage. Record and report the measured dimensions and locations of the measurements for use in the calculation of the flexure stress. For the three-point loading geometry, use the dimensions at the center force application point in the stress calculations. For four-point loading geometries, use the average of the multiple measurements in the stress calculations.

10.2 In some cases it is desirable, but not required, to measure surface finish to quantify the condition of as-prepared and finished surfaces. Such methods as contacting profilometry can be used to determine surface roughness along the tensile surface and parallel to the tensile axis. When quantified, surface roughness shall be reported.

10.3 *Test Modes and Rates*—Test modes and rates may have distinct and strong influences on fracture behavior of advanced

ceramics even at ambient temperatures depending on test environment or condition of the test specimen. Test modes may involve force, displacement, or strain control. Recommended rates of testing are projected to be sufficiently rapid to obtain the maximum possible flexural strength of the material. However, rates other than those recommended herein may be used to evaluate rate effects. In all cases, report the test mode and rate.

10.3.1 For monolithic advanced ceramics exhibiting linear elastic behavior, fracture is characterized by a weakest-link fracture mechanism generally attributed to stress-controlled fracture from Griffith-like flaws. Therefore, a force-controlled test, with force generally related directly to tensile stress, is the preferred test control mode. However, the nonlinear stress-strain behavior characteristic of the graceful fracture process of CFCCs indicates a cumulative damage process which is strain dependent. Generally, displacement or strain controlled-tests are employed in such cumulative damage or yielding deformation processes to prevent a “runaway” condition (that is, rapid uncontrolled deformation and fracture) characteristic of force or stress controlled tests. Thus, to identify the potential toughening mechanisms under controlled fracture of the CFCC, displacement or strain control may be preferred. However, for sufficiently rapid test rates, differences in the fracture process may not be apparent and any of these test control modes may be appropriate.

10.3.2 *Strain Rate*—Strain is the independent variable in nonlinear mechanisms such as yielding. As such, strain rate is a method of controlling tests of deformation processes to avoid runaway conditions. For the linear elastic region of CFCCs, strain rate can be related to stress rate such that:

$$\dot{\epsilon} = d\epsilon/dt = \sigma/E \quad (1)$$

where:

$\dot{\epsilon}$ = the strain rate in the units of s^{-1} ,

ϵ = the maximum strain in the outer fibers,

t = time in units of s,

$\dot{\sigma}$ = the maximum stress rate in the outer fibers in units of $MPa s^{-1}$, and

E = the elastic modulus of the CFCC in units of MPa.

Strain-controlled tests can be accomplished using a deflectionometer contacting the center line of the inner support span of the test specimen to produce the control signal. Strain rates on the order of 500×10^{-6} to $5000 \times 10^{-6} s^{-1}$ are recommended to minimize environmental and force application rate effects when testing in ambient air. Alternately, strain rates shall be selected to produce final fracture in 5 to 10 s to minimize environmental and force application rate effects. Elevated testing temperatures may enhance the environmental or force application rate effects, or both. Minimize those effects by increasing the strain rate if the initial material evaluation shows such effects.

10.3.3 *Displacement Rate*—The differences in size of each test specimen geometry require a different cross-head rate for an assigned strain rate. Note that as the test specimen begins to deform in a nonlinear mode, the strain rate in the outer fibers of the test specimen will change even though the rate of motion of the cross head remains constant. For this reason, displacement rate controlled tests can give only an approximate value

of the imposed strain rate. Displacement control mode is defined as the control of, or free-running displacement of, the test machine cross head to mechanically apply force to the test specimen. [Table 1](#), [Table 2](#), or [Table 3](#) provide displacement rates for a nominal strain rate of $1000 \times 10^{-6} \text{ s}^{-1}$ for the different test geometries. If the tables are not used, calculate the rate of cross-head displacement as follows, depending on test geometry used.

$$\text{Test Geometry I (3-Point)} \quad \dot{D} = 0.167 \epsilon L^2/d \quad (2)$$

$$\text{Test Geometry IIA (4-Point-}\frac{1}{4}\text{ Point)} \quad \dot{D} = 0.167 \epsilon L^2/d \quad (3)$$

$$\text{Test Geometry IIB (4-Point-}\frac{1}{3}\text{ Point)} \quad \dot{D} = 0.185 \epsilon L^2/d \quad (4)$$

where:

\dot{D} = rate of cross-head motion, mm/s (for rates in mm/min, multiply by 60),

L = outer support span, mm,

d = test specimen thickness, mm, and

ϵ = desired strain rate of the outer fiber, mm/mm-s.

A strain rate of $1000 \times 10^{-6} \text{ s}^{-1}$ is recommended for initial testing.

10.4 Conducting the Flexure Test:

10.4.1 At the start of each test sequence, assemble and align the appropriate flexure test fixture in the required testing configuration. Align and measure the force application point locations so that inner and outer support spans are within 1 % of the required position values.

10.4.2 *Test Specimen Loading for Ambient Testing*—Mark the test specimen with an indelible marker as to top and bottom surfaces at points beyond the outer support span. This will assist in later identifying tensile and compressive loaded faces. Carefully place each test specimen into the test fixture to preclude possible damage and to ensure alignment of the specimen in the test fixture.

10.4.3 *Test Specimen Loading for Elevated-Temperature Testing*—The test specimen may be loaded into either a cold furnace with the whole system then heated to operating temperature or directly into a hot furnace. In hot furnace loading, take care to minimize or eliminate the thermal shock damage to the test specimen. See [Annex A3](#) for discussion of hot furnace loading issues.

10.4.3.1 Raise the temperature of the test furnace linearly to the test temperature within a period of 20 ± 5 min. Ensure that overshoot of the test temperature does not exceed 5°C for test temperatures below 500°C and 1 % for test temperatures above 500°C and does not exceed a duration of 15 s. Stabilize the test temperature for a duration of 20 ± 5 min prior to applying force to the test specimen. Temperature overshoot shall be included in timing the stabilization period. Record any temperature excursions occurring after the overshoot which exceed 1 % of the test temperature.

10.4.4 *Preparations for Testing*—Set and check the cross-head displacement rate on the test machine. Set and check the data collection system for data logging. Position, check, and zero the displacement/strain measuring system.

10.4.5 Preload the test specimen to remove the slack from the load train. The amount of preload will depend on the

material and test specimen geometry, and therefore must be determined for each situation. Preload shall not exceed 5 % of the breaking strength. For ambient condition testing, check the contact between the bearings and the specimen to ensure even-line force application across the width of the specimen. For ambient testing, mark the specimen to identify the points of force application and the front face of the specimen. Carefully drawn colored pencil marks are suitable. The marks are used as a reference to locate the point of fracture.

10.4.6 Determine and record the ambient temperature and the relative humidity in accordance with Test Method [E 337](#).

10.4.7 *Conducting the Test*—Determine and record the test temperature. Initiate the data acquisition. Start the force application. Continue the test until the specimen breaks into two pieces or there is a drop of 20 % from the maximum observed force. Record the maximum force and the fracture force. After test completion disable the action of the test machine and the data acquisition system. For elevated-temperature tests, permit the sample and furnace to cool to a suitable handling temperature. Carefully remove the fractured specimen and any fragments from the test fixture, and retain them for later analysis. Take care not to damage the fracture surfaces by preventing them from contact with each other or other objects.

10.4.8 Note the general location of the fracture point (center, left/right of center, out-of-span). If measured fracture location data is desired, measure and report the fracture location relative to the support span to ± 1 mm. Use the convention that the midpoint between the two outer spans is 0 mm with positive (+) measurements toward the right of the specimen as tested (and marked) and negative (–) measurements toward the left of the specimen as tested (and marked).

10.4.9 In addition to the location, carefully note the mode of the fracture initiation and crack extension. Fracture may initiate on the tensile (lower) face, on the compression (upper) face of the bar, or by shear failure (see [Fig. 4](#)). The bar may fail by a sequential combination of modes. The tensile fracture crack may extend toward the neutral axis directly or may deflect along low-strength planes such as interlaminar regions.

10.4.10 *Invalid Tests*—In Test Geometry I (three-point testing), failure may occur beyond the point of maximum stress (2 mm or 5 % of the outer-span length away from the center point, whichever is greater). Note and record data from such a failure as invalid data. Invalid data shall be reported as such, but not used to calculate average values.

10.4.10.1 Anomalous failures may also occur by two other mechanisms that invalidate the test. The first mechanism is by crushing under the bearing points. The second mechanism is by shear failure in regions of high shear stress and low shear strength, that is, interlaminar regions in 2-D composites. Shear failure in laminates is observed as delamination/tearing between plies in high shear strain regions (see [Fig. 4](#)).

10.4.10.2 Note that results from anomalous fractures cannot be used in the direct calculation of a mean flexural strength at fracture for the test set. Results from such tests can be noted as invalid tests. To complete a required statistical sample (for

FIG. 4 Modes of Fracture in Flexure Testing

example, $n = 10$) for purposes of average strength, test one replacement specimen for each test specimen that failed in an invalid manner.

10.4.11 Visual examination and light microscopy should be conducted to determine the mechanism and type of fracture (that is, brittle or fibrous). In addition, although quantitatively beyond the scope of this test method, observations can be made of the length of fiber pullout, crack deflection, orientation of fracture plane, degree of interlaminar fracture, and other pertinent details of the fracture extension and morphology.

10.4.12 Fractographic examination of each failed test specimen is recommended to characterize the fracture behavior of CFCCs. Clearly note and describe in the test report if a fractographic analysis is performed.

11. Calculation of Results

11.1 General—Different types of CFCC material may exhibit vastly different stress-strain responses due to the nature of their constituents, fabrication methods, and prior mechanical/environmental history. Examples of different stress-strain curves are shown in Fig. 5a through 5c. Interpretation of the stress-strain will depend on the type of response exhibited. Points on the stress-strain curves corresponding to the following calculated values are shown in Fig. 5a through 5c.

11.2 Flexure Calculations—When a beam of homogeneous, elastic material is tested in flexure as a simple beam, the maximum stress occurs in the outer fibers. For the sake of calculating the flexure stress and strain of ceramic matrix composites, the simplifying assumptions of homogeneous and elastic properties are made for these tests.

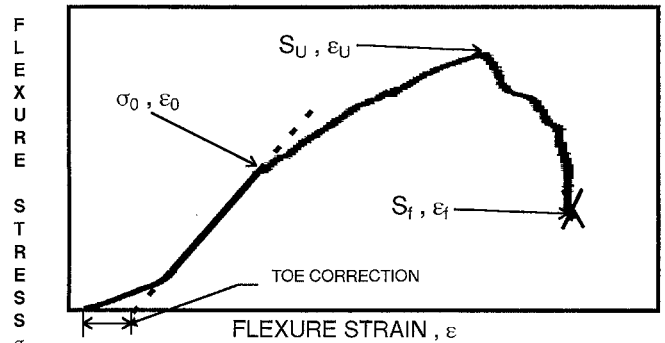

NOTE 3—In the strictest sense, the elastic beam equations apply only to materials for which the stress is linearly proportional to strain up to the point of rupture and for which the plane sections remain plane and the deflections are small. Since this is not always the case for ceramic matrix composites, errors will be introduced. However, the use of the equations is appropriate for comparison data and specification values up to the maximum fiber strain of 5 %.

11.3 Flexure Stress (σ)—When tested in flexure, a simple beam experiences the maximum tensile/compressive stresses in the outer fibers. The location of maximum stress along the length of the beam is at the center point for three-point testing and in the center of the inner support span for four-point testing. Equations for calculating the flexure stress for the three test geometries (I, IIA, and IIB) are given in Table 4.

11.4 Flexure Strain (ϵ)—The flexure strain for a designated flexure stress is calculated using the outer support span, the

a) Stress-Strain Curve with a Linear Region

b) Stress-Strain Curve with a Linear Region and a Toe

c) Stress-Strain Curve with a Nonlinear Region

FIG. 5 Schematic Diagrams of Flexural Stress-Strain Curves for CFCCs

deflection, and the test specimen thickness. Equations for

σ	= maximum stress in the outer fibers at a given force (MPa)		P
L	= outer support span (mm)		b
d	= test specimen thickness (average or at point of break) (mm)		ϵ
D	= deflection at beam center at a given point in the test (mm)		S_U
P_U	= maximum force in the flexure test (N)		ϵ_{UJ}
D_{UJ}	= deflection at beam center at maximum force (mm)		S_F
P_F	= breaking force in the flexure test (N)		ϵ_{FJ}
D_{FJ}	= deflection at beam center at fracture force (mm)		E
m	= slope of tangent to the initial straight-line portion of the force-deflection curve (N/mm)		= force at given point in the test (N)
			= test specimen width (average or at center point) (mm)
			= maximum strain in the outer fibers at a given force (mm/mm)
			= flexural strength at maximum force (MPa)
			= strain at flexural strength (mm/mm)
			= fracture strength at breaking force (MPa)
			= strain at fracture strength (mm/mm)
			= modulus of elasticity in bending (MPa)

calculating the flexure strain for the three test geometries (I, IIA, and IIB) are given in **Table 4**.

11.4.1 Note that in some cases the initial portion of the curve shows a nonlinear region or “toe” followed by a linear region as shown in **Fig. 5b**. This toe may be an artifact of the test specimen or test conditions (for example, straightening of a warped test specimen) and thus does not represent a property of the material. The curve can be corrected for this toe by the method described in **Annex A4**. The correction shall then be used for all measurements of deflection and strain.

11.5 *Flexural Strength (S_U)*—The flexural strength is equal to the maximum stress in the outer fibers at the point of maximum force. It is calculated using the equations given in **Table 4** for the three test geometries.

11.5.1 *Flexural Strength (S_U) for Beams Tested at Large Outer Support Spans*—If span-to-depth ratios are large enough that deflections in excess of 10 % of the outer support span occur in the test, the elastic equations for stress must be modified for nonlinear effects (see **Note 4**). Under those conditions the flexural strength is calculated using the modified equations in **Table 5**.

TABLE 5 Stress Calculations for Beams Tested at Large outer support spans (per 11.5.1)

Flexural Strength S_U	
Test Geometry I 3-point	$S_U = (3 P_U/L(2 bd^2) \times (1 + 6 (D_U/L)^2 - 4 d (D_U/L^2))$
Test Geometry II-A 4 point-¼ point	$S_U = (3 P_U/L(4 bd^2) \times (1 - 10.19 d (D_U/L^2))$
Test Geometry II-B 4 point-⅓ point	$S_U = (P_U/L(bd^2) \times (1 + 4.70 (D_U/L)^2 - 7.04 d (D_U/L^2))$
Fracture Strength S_F	
Test Geometry I 3-point	$S_F = (3 P_F/L(2 bd^2) \times (1 + 6 (D_F/L)^2 - 4 d (D_F/L^2))$
Test Geometry II-A 4 point-¼ point	$S_F = (3 P_F/L(4 bd^2) \times (1 - 10.19 d (D_F/L^2))$
Test Geometry II-B 4 point-⅓ point	$S_F = (P_F/L(bd^2) \times (1 + 4.70 (D_F/L)^2 - 7.04 d (D_F/L^2))$

NOTE 4—When large outer support span-to-depth ratios are used, significant end forces are developed at the supports that affect the moment in a simply supported beam. Approximate correction factors are given in **Table 5** to correct for these end forces in beams with large span-to-depth ratios, where relatively large deflections exist.

11.6 *Strain at Flexural Strength (ϵ_{UJ})*—The strain at the point of maximum force is calculated using the equations given in **Table 4** for the three test geometries.

11.7 *Fracture Strength (S_F)*—The fracture strength is equal to the stress in the outer fibers at the force when the test specimen separates into two or more segments or the force drops by 20 % from the maximum force without the sample clearly separating. In some cases, the fracture strength and the flexure strength may be defined by the same force value.

11.7.1 *Fracture Strength (S_F) for Beams Tested at Large Outer Support Spans*—If span-to-depth ratios are large enough that deflections in excess of 10 % of the outer support span occur in the test, the elastic equations must be modified for nonlinear effects (see **Note 4**). Under those conditions, the fracture strength is calculated using the modified equations in **Table 5** for the three test geometries.

11.8 *Strain at Fracture Strength (ϵ_{FJ})*—The strain at the force at which the test specimen separates into two or more segments or the force has dropped by 20 % from the maximum force. It is calculated using the equations given in **Table 4** for the three test geometries.

11.9 *Modulus of Elasticity by Tangent (E)*—The tangent modulus of elasticity is the ratio (within the elastic limit) of stress to corresponding strain and shall be expressed in MPa. It is calculated by drawing a tangent to the steepest initial straight-line portion of the force-deflection curve and using the equations given in **Table 4** for the different test geometries. Note that the tangent modulus of elasticity may not be defined for materials that exhibit entirely nonlinear curves as shown in **Fig. 5c**.

11.10 *Proportional Limit Stress*—Determine the proportional limit stress, σ_0 , by one of the following methods:

11.10.1 *Offset Method*—Determine the proportional limit stress by generating a line running parallel to the same part of the linear part of the curve used to determine the modulus of

elasticity in 11.9. The line so generated shall be at a strain offset of 0.0005 mm/mm. The proportional limit stress is the stress level at which the offset line intersects the curve (see Fig. 6). Note that for the off-set method, the proportional limit stress may not be defined for materials which exhibit entirely nonlinear curves as shown in Fig. 5c.

11.10.2 *Extension Under Force Method*—Determine the proportional limit stress by noting the stress on the curve that corresponds to a specified strain (see Fig. 6). The specified strain is selected based on design or performance requirements appropriate for the material tests. The specified strain may or may not be in the linear region of the stress-strain curve. The specified strain at which the proportional limit stress is determined shall be constant for all tests in a set. The specified strain shall be reported for the proportional limit stress.

11.11 *Strain at Proportional Limit Stress*—Determine the strain at proportional limit stress as the strain corresponding to the proportional limit stress (see Fig. 6).

11.12 *Equation Corrections for Elevated-Temperature Testing*—The equations shown in Table 4 and Table 5 do not compensate for thermal expansion of the fixture and test specimen at elevated-temperature testing, since all dimensions are taken at room temperature. At elevated testing temperatures, expansion of the fixture and test specimen can lead to errors of 1 to 3 % for advanced ceramics if the equations are not corrected. Annex A5 provides the correction factors for the dimensions in Table 4 and Table 5 and shall be used if the average thermal expansion coefficient of the fixture and the test specimen are known. The use of the thermal expansion corrected equations shall be stated explicitly in the report.

11.13 *Mean, Standard Deviation, and Coefficient of Variation*—For each series of tests, the mean, standard deviation, and coefficient of variation for each measured value can be calculated as follows:

$$\text{Mean} = \bar{X} = \left[\left(\sum_{i=1}^n X_i \right) / n \right] \quad (5)$$

$$\text{Standard deviation} = sd = \sqrt{ \left[\left(\sum_{i=1}^n (X_i - \bar{X})^2 \right) / (n - 1) \right] } \quad (6)$$

$$\text{Coefficient of variation} = CV = 100 (sd) / \bar{X} \quad (7)$$

where:

X = the measured value, and

n = the number of valid tests.

12. Report

12.1 *Test Set*—The report shall include the following information for the test set. Any significant deviations from the procedures and requirements of this test method shall be noted in the report.

12.1.1 Date and location of testing and name of test operator.

12.1.2 Geometry of the flexure test specimen (include engineering drawing, if necessary) specifying tolerances and surface finish requirements.

12.1.3 Type and configuration of the test machine (include drawing or sketch, if necessary). If a commercial test machine was used, the manufacturer and model number are sufficient for describing the test machine.

12.1.3.1 The force capacity and accuracy of the load cell.

12.1.3.2 The method of data collection.

12.1.4 Furnace description to include method of temperature measurement and atmosphere.

12.1.5 Type, configuration, and resolution of displacement/strain measurement equipment used (include drawing or sketch if necessary). If commercial displacement or strain gages were used, the manufacturer and model number are sufficient for describing the strain measurement equipment.

12.1.6 Test control mode (force, displacement, or strain control) and actual test rate (force rate, displacement rate, or strain rate). Calculated strain rate shall also be reported, if appropriate, in units of s^{-1} .

12.1.7 Description of the loading geometry (3 pt, 4 pt-1/4 pt, 4 pt-1/3 pt) to include outer support span and span-to-depth ratio. Description of fixture materials and support point geometries. If a commercial fixture was used, the manufacturer and model number are sufficient for describing the fixture. Describe the articulation of the loading fixture and whether the bearings were free to roll or fixed.

12.1.8 Complete identification of the material tested, including type, source, manufacturer's code number, form, and history.

12.1.9 All relevant material data including vintage data or billet identification data. (Did all test specimens come from one billet or processing run?) As a minimum, the date the material was manufactured shall be reported. For commercial materials, the commercial designation shall be reported. As a minimum for commercial materials, include a short description of the composite composition—matrix, reinforcement (type, layup, etc.), fiber volume fraction, and bulk density.

12.1.9.1 For noncommercial materials, the major constituents and proportions shall be reported as well as the primary processing route, including green state and consolidation/densification methods. Also report fiber volume fraction, matrix porosity, and bulk density. The reinforcement composition, properties and architecture shall be fully described to include fiber properties (composition, diameter, source, lot number, and any measured/specified properties), interface coatings

FIG. 6 Schematic Diagram of Methods for Determining Proportional Limit Stress

(composition, thickness, morphology, source, and method of manufacture) and the reinforcement architecture (yarn type/count, thread count, weave, ply count, fiber areal weight, stacking sequence, ply orientations, etc.).

12.1.9.2 Description of the method of test specimen preparation including all stages of machining. A cutting diagram showing the location of individual samples as cut from the original as-fabricated test specimen.

12.1.9.3 Heat treatments, coatings, or pre-test exposures, if any, applied either to the original as-processed material or to the as-prepared flexure test specimens.

12.1.9.4 The results of the general examination described in 9.5, that is, nonuniformity in major dimensions; warp, twist, and bowing; porosity (volume percent and size distribution); discontinuities such as delaminations, cracks, etc; and surface roughness on as-prepared and finished surfaces. The results and method of any surface finish measurements. The results of any nondestructive evaluations.

12.1.10 Test environment including ambient temperature and relative humidity (Test Method E 337), test temperature, and test chamber atmosphere (for example, ambient air, dry nitrogen, argon, etc.). For elevated-temperature testing, include mode of sample insertion, heating rate, and soak/hold time at temperature.

12.1.11 Number (n) of test specimens tested validly (for example, fracture in the gage section). In addition, report the total number of test specimens tested (n_T) to provide an indication of the test success rate for the particular test specimen geometry, material, and test apparatus.

12.1.12 Mean, standard deviation, and coefficient of variation (to three significant figures) for each test series of the following test measurements:

- 12.1.12.1 Flexural strength,
- 12.1.12.2 Strain at flexural strength,
- 12.1.12.3 Fracture strength,
- 12.1.12.4 Strain at fracture strength,
- 12.1.12.5 Modulus of elasticity, E (if determined),
- 12.1.12.6 Proportional limit stress, (if determined) and method of determination, and
- 12.1.12.7 Strain at proportional limit stress, (if determined).

12.2 *Individual Test Specimens*—The report shall include the following information for each test specimen tested:

12.2.1 *Test Specimen Dimensions*—Length, width, and thickness in units of mm. For three-point testing, the center dimension should be used for calculations. For four-point testing, the multiple measurements should be reported and averaged and used for calculation.

12.2.2 Plot of the entire force-displacement or stress-strain curve.

- 12.2.3 Flexural strength.
- 12.2.4 Strain at flexural strength.
- 12.2.5 Fracture strength.
- 12.2.6 Strain at fracture strength.
- 12.2.7 Modulus of elasticity, E (if determined).
- 12.2.8 Proportional limit stress, (if determined) and method of determination.

- 12.2.9 Strain at proportional limit stress, (if determined).
- 12.2.10 Maximum force.

12.2.11 Displacement at maximum force.

12.2.12 Fracture location relative to the test specimen midpoint. If the location is measured, the data shall be reported in units of mm (plus is toward the right of the test specimen as marked and minus is toward the left of the test specimen as marked with zero being the test specimen section midpoint).

12.2.13 *Failure Mode*—Tensile, compression, shear, crushing under the bearings, or mixed modes, as described in 10.4.10.

12.2.14 Appearance of test specimen after fracture and a description of fiber pull-out as suggested in 10.4.11 and 10.4.12.

12.2.15 Average surface roughness, if measured, of sample surfaces in the support span.

12.3 An example of a test report form is given in Appendix X1.

13. Precision and Bias

13.1 The flexural strength of a ceramic composite is not a deterministic quantity, but will vary from one specimen to another. This variability is based on the inherent variations in ceramic composites made with fiber reinforcement. Variables include property/morphology variations in fibers, matrix, and interface coatings, as well as variations in the architecture, reinforcement volume fraction, and density in the composite. Such variations can occur spatially within a given test specimen, as well as between different test specimens.

13.2 A multiple laboratory round-robin test³ was conducted in 1998 to determine the precision of flexural properties for a commercially available continuous fiber-reinforced ceramic composite. Repeatability and reproducibility were assessed for flexural strength, flexural failure strain, and elastic modulus for 100 test specimens tested in sets of 10 by 10 different laboratories. Bias was not evaluated because there is no commonly recognized standard reference material for continuous fiber-reinforced ceramic composites.

13.2.1 Flexure test specimens were cut from four panels of a commercial Trademark Sylramic⁴ S-200* ceramic composite. The panels were fabricated with eight plies of ceramic grade (CG)-Trademark Nicalon⁵ fabric (8-Harness Satin) in a silicon-carbonitride matrix (based on a preceramic polymer) with a silicon nitride powder filler. The ply architecture was a symmetric 0/90 lay-up (0/90/0/90/90/0/90/0). The Nicalon fibers had a proprietary boron nitride interface coating. The finished composites had a nominal fiber volume fraction of 45 volume percent, a measured mean bulk density of 2.21 g/cm³, and a mean open porosity of 2.7 %. The flexure test specimens were 110 by 9 mm with an as-fabricated, average thickness of 2.74 mm. The 100 test specimens were randomly divided into groups of ten for distribution to and testing by the ten participating laboratories.

13.2.2 Round-robin participants tested the test specimens using a four-point flexure geometry with an 80-mm outer span

³ Manufactured by Dow Corning Corp., Midland, MI, 1998. As of January 2006, manufactured by ATK-COI Ceramics, San Diego, CA.

⁴ Sylramic is a registered trademark of ATK-COI Ceramics.

⁵ Nicalon is a registered trademark of Nippon Carbon Co., Ltd.

and a 40-mm inner span (a span-to-depth ratio of 29), a cross head rate of 0.10 mm/s, deflection control mode, and at ambient temperature and humidity.

13.2.3 A statistical analysis of the flexural test data for this specific batch of ceramic composite test specimens was conducted using Practice E 691. All the data for flexural strength, flexural failure strain, and elastic modulus were judged as valid in accordance with Practice E 691 criteria. Based on the data analysis, the repeatability and reproducibility statistics for the ASTM C 1341 Flexural Properties of Continuous Fiber-Reinforced Advanced Ceramic Composites are shown in Table 6.

13.2.4 The repeatability and reproducibility values determined in the cited study are specific to the particular ceramic composite test specimens (composition, architecture, and lot) tested in the study and tested in accordance with the cited geometry and test protocols. Tests on different ceramic composite test specimens with different geometries and test protocols may have different repeatability/reproducibility values.

13.3 Mechanical test data for ceramic matrix composites can vary based on variations in experimental procedures between laboratories and for variations in material thickness, density, and porosity among the test specimens and between lots. Reference 6 analyzes the variation in mechanical properties against the variations among test specimens and variations in test methods between laboratories.

TABLE 6 Flexural Data and Repeatability/Reproducibility Analysis Trademark Sylicamic S-200 Ceramic Composites Tested ASTM C 1341

	Flexural Strength	Flexural Failure Strain	Elastic Modulus
Mean value for the 10 laboratories	338.6 MPa	0.464 %	93.0 GPa
Repeatability—Mean of the coefficient of variation (CV) of the ten laboratories	9.9 %	14.1 %	4.4 %
Reproducibility—Coefficient of variation (CV) between the ten laboratories	11.1 %	13.6 %	7.1 %
95 % repeatability limit (within laboratory), 2.8 CV % ^A	27.7 %	39.5 %	12.3 %
95 % reproducibility limit (between laboratories) 2.8 CV % _R ^A	31.1 %	38.1 %	19.9 %

^A Calculated in accordance with Practice E 691, Section 21, and reported in accordance with Practice E 177, Section 28.

13.4 A “propagation of errors” study showed that measurement of specimen thickness is a critical source of variability, because flexure and elastic modulus values are calculated by equations which use thickness values to the 2d and 2d power, respectively. In addition, the thickness dimension is generally the smallest dimension and most susceptible to experimental variation in and between laboratories.

14. Keywords

14.1 ceramic matrix composite; CFCC; continuous fiber composite; flexural strength; flexure test; modulus of elasticity

ANNEXES

(Mandatory Information)

A1. COMPLIANCE DETERMINATION

A1.1 Typically, the compliance of the test set-up [$C_m = (D/P)_m$, where m is machine] is measured using a thick block of rigid material (for example, sintered α silicon carbide in a 12 by 25 by 50 mm block) which is essentially noncompliant relative to the load train. When the testing system is forced using the thick block in place of a test specimen, the compliance of the test system is determined from the force (P) versus cross-head displacement (P_{x-head}) measurements such that:

$$C_m = (D/P)_m \sim (D_{x-head}/P) \quad (A1.1)$$

If cross-head displacement is used to determine the test specimen deflection for the three-point loading geometry, the test specimen deflection (D) at a given force (P_x) is determined by subtracting the machine deflection (calculated as $P_x C_m$) from the cross-head deflection (D_{x-head}):

$$D = D_{x-head} - (P_x C_m) \quad (A1.2)$$

A2. CFCC SURFACE CONDITION AND FINISHING

A2.1 *Finishing Method*—Because there are no universal or standard practices for finish machining of CFCCs, the following categories of test specimen condition/finish shall be used for sample preparation and description.

A2.2 *As-Fabricated*—The flexure test specimen should simulate the surface/edge conditions and processing route of an application where no machining is used, for example, as-cast, sintered, or injection molded part. No additional machining specifications are relevant. As-processed test specimens might possess rough surface textures and nonparallel edges and as

such may cause excessive misalignment or be prone to nongage section fractures, or both.

A2.3 *Application-Matched Machining*—The flexure test specimen should have the same surface/edge preparation as that given to the component. Unless the process is proprietary, the report shall be specific about the stages of material removal, wheel grits, wheel bonding, amount of material removed per pass, and type of coolant used.

A2.4 *Customary Practices*—In instances where a manufacturer or user has defined a customary machining procedure that

is completely satisfactory for a class of CFCC materials (that is, it induces no unwanted surface/subsurface damage or residual stresses), that procedure should be used.

A2.5 *Standard Procedure*—In instances where A 2.2 through A 2.4 are not appropriate, A 2.5 shall apply. Studies to evaluate the machinability of CFCCs have not been completed. Therefore, the standard procedure of A 2.5 can be viewed as starting-point guidelines, and a more stringent procedure may be necessary.

A3. CONDITIONS AND ISSUES IN HOT FORCE APPLICATION OF TEST SPECIMENS INTO FURNACES

A3.1 The following issues and concerns shall be considered in designing and using hot-force-application procedures for specimen testing.

A3.2 The fixtures may be either left in the furnace at all times or removed partially or completely for force application and insertion, depending on the design of furnace system.

A3.3 Some furnaces are amenable to hot force application, but care shall be taken to avoid thermally shocking the furnace or test fixtures. A furnace with a small convenient portal is generally best since the heat loss and radiation will be minimized. This makes it easier to force, and the furnace will return to operating temperature more rapidly.

A3.4 Suitable precautions shall be taken to ensure operator

A2.5.1 All grinding or cutting shall be done with ample supply of appropriate filtered coolant to keep the workpiece and grinding wheel constantly flooded and particles flushed. Grinding can be done in at least two stages, ranging from coarse to fine rate of material removal. All cutting can be done in one stage appropriate for the depth of cut.

A2.5.2 Stock removal rate shall be on the order of 0.03 mm per pass using diamond tools that have between 320 and 600 grit. Remove equal stock from each face where applicable.

safety from the hazards of thermal or electrical burns. Thermal gloves, long insertion tools, and protective/darkened face shield are essential.

A3.5 Ensuring proper test specimen placement may be more difficult when forcing into a hot system, but this can be offset by the use of a suitable self-aligning jig. A rolling-pin fixture poses further difficulties, since it is essential that the rollers and test specimens are positioned properly. Again, this can be accomplished with careful fixture design. For example, removable inserts could be used to hold the rollers in proper position, the test specimen inserted and preloaded, and then the inserts removed. In some instances, it is possible to use common acetate household cement to hold the rollers in place in a cold fixture during the insertion procedure. Such cement burns off, leaving no residue.

A4. TOE COMPENSATION ON STRESS-STRAIN CURVES

A4.1 In a typical stress-strain curve (Fig. A4.1) there is a toe region (AC) that does not represent a property of the material. It is an artifact caused by a takeup of slack and alignment or seating of the test specimen. In order to obtain correct values of such parameters as modulus, strain, and offset

yield point, this artifact shall be compensated for to give the corrected zero point on the strain or extension axis.

A4.2 In the case of a material exhibiting a region of Hookean (linear) behavior (Fig. A4.1), a continuation of the linear (CD) region of the curve is constructed through the zero-stress axis. This intersection (B) is the corrected zero-strain point from which all extensions or strains shall be measured, including the yield offset (BE), if applicable. The elastic modulus can be determined by dividing the stress at any point along the line CD (or its extension) by the strain at the same point (measured from point B, defined as zero strain).

A4.3 In the case of material that does not exhibit any linear region (Fig. A4.2), the same kind of toe correction of the zero strain point can be made by constructing a tangent to the maximum slope at the inflection point (G'). This is extended to intersect the strain axis at point B', the corrected zero strain point. Using point B' as zero strain, the stress at any point (H') on the curve can be divided by the strain at that point to obtain a secant modulus (slope of line B' H'). For those materials with no linear region, any attempt to use the tangent through the inflection point as a basis for determination of an offset yield point may result in unacceptable error.

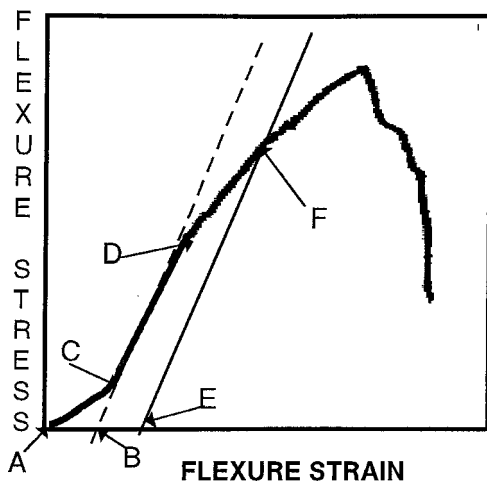

FIG. A4.1 Stress-Strain Curve for a Material with a Hookean Region

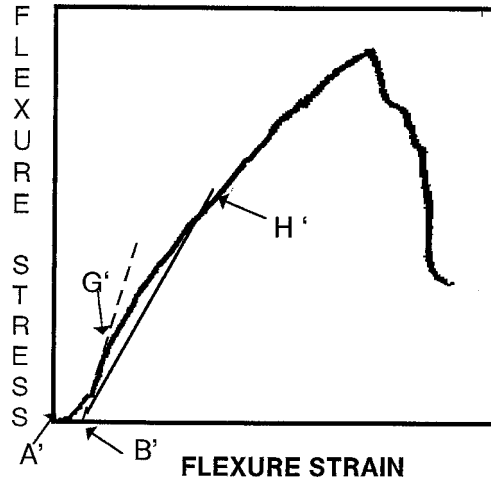

FIG. A4.2 Stress-Strain Curve for a Material with No Hookean Region

A5. CORRECTIONS FOR THERMAL EXPANSION IN FLEXURAL EQUATIONS

A5.1 The following correction factors shall be used for the dimensions *L*, *b*, and *d* for the equations in Table 4 and Table 5 if the thermal expansion of the fixtures and test specimen are known.

$$L_{corrected} = L (1.0 + \alpha_{fix} \Delta T) \quad (A5.1)$$

$$b_{corrected} = b (1.0 + \alpha_{spec-b} \Delta T) \quad (A5.2)$$

$$d_{corrected} = d (1.0 + \alpha_{spec-d} \Delta T) \quad (A5.3)$$

α_{spec-b} = average coefficient of thermal expansion from room temperature to the test temperature for the test specimen material in the width direction, °C⁻¹,

α_{spec-d} = average coefficient of thermal expansion from room temperature to the test temperature for the test specimen material in the thickness direction, °C⁻¹.

where:

- L* = outer support span, mm,
- b* = test specimen width (average or at center point), mm,
- d* = test specimen thickness (average or at center point), mm,
- α_{fix} = average coefficient of thermal expansion from room temperature to the test temperature for the test fixture material, °C⁻¹,

NOTE A5.1—The thermal expansion coefficient may be different in the two cross-sectional dimensions of the sample if the sample has an anisotropic architecture.

ΔT = temperature difference from room temperature to test temperature, °C.

APPENDIX

(Nonmandatory Information)

X1. EXAMPLE OF A TEST REPORT

X1.1 The following is the example of the test report as mentioned in 12.3. See Fig. X1.1.

Test Date and Location _____ Name of test operator _____ Laboratory Identification _____

TEST EQUIPMENT DESCRIPTION

Test Machine Manufacturer _____ Load cell capacity and accuracy _____
 Model #, & Configuration _____
 Displacement/strain measurement method _____ Method of data collection _____
 Furnace description _____

to include temperature measurement method, atmosphere, and method of heating

Loading fixture geometry (3 pt, 4pt-1/4 pt, 4pt 1/3 pt) _____ Manufacturer & Model _____
 Description of fixture geometry and materials _____
 Articulated _____ Free moving rollers? _____ Roller Diameter (mm) _____
 Outer span length (mm) _____ Load Span length (mm) _____ (NA for 3-point)

TEST MATERIAL DESCRIPTION

Material Name & Description _____
 Source _____ Billet identification data _____ Date of Manufacture _____
 Material Description & History (per section 12.1.9 & 10) _____

Flexure specimen dimensions (mm) _____ Tolerances and surface finish requirements _____
 (include engineering drawing if available) Measured Surface Roughness _____
 Method of specimen preparation/machining _____
 (Cutting diagram if available) Fiber/Fabric Alignment Angle (to long axis of test bar) _____
 Heat treatments, coatings, or pre-test exposures _____

General examination results (per Section 9.5) _____

NDE Methods & Results _____

Any significant deviations from the test method _____

NOTE 1—Plots of the force-displacement or stress-strain curves and any fractographic analysis results shall also be included.

FIG. X1.1 Test Report

TEST PROCEDURE

Test temperature (C) _____ Test Atmosphere _____ Ambient Temp _____ Relative humidity _____

For elevated-temperature testing,
 Mode of sample insertion _____ Heating rate _____ Soak/hold time _____
 Test mode and test rate (displacement, strain, or load rate) _____ Calculated strain rate in units of s⁻¹ _____
 Span-to-depth ratio _____ Specimen Orientation _____

Number (n) of specimens tested validly _____ Total number (n_T) of specimens tested _____

TEST DATA SUMMARY (TEST ID # _____)

TEST RESULTS	MEAN	STANDARD DEVIATION	COEFFICIENT OF VARIATION
Flexural Strength, S _U , MPa			
Strain at Flexural Strength, ε _U			
Fracture Strength, S _F , MPa			
Strain at Fracture Strength, ε _F			
Modulus of Elasticity, E (if determined), GPa			
Proportional Limit Stress, σ _O , MPa (if determined) and method of determination			
Strain at Proportional Limit Stress, ε _O (if determined)			

FIG. X1.1 Test Report (continued)

INDIVIDUAL SPECIMEN DATA (TEST ID # _____)

Specimen ID #											Mean	Std.Dev
Spec. Width(mm)												
Spec. Thick(mm)												
Max. Load (N)												
Displacement at Max Load (mm)												
Flexural Strength (MPa)												
Strain at Flexural Strength												
Fracture Strength (MPa)												
Strain at Fracture Strength												
Modulus of Elasticity (GPa)												
Proportional Limit Stress (MPa)												
Strain at Proport. Limit Stress												
Fracture Location ¹												
Failure Mode ²												
Fracture Surface Appearance ³												

- 1 - Fracture Location -- Center, within loading span, outside loading span
 2 -- Failure Mode -- tensile, compression, shear, load point crushing , mixed
 3 -- Fracture Surface Appearance -- fibrous, brittle
